## Softmax function

#### Kristian Wichmann

May 2, 2017

#### 1 Definition

Given an n-dimensional input vector z, the softmax function (also known as the normalized exponential function), has the output:

$$\sigma_i(z) = \frac{e^{z_i}}{\sum_{k=1}^n e^{z_k}} \tag{1.1}$$

This means, that the outputs can be interpreted as an discrete probability distribution, since they will always sum to 1.

It will be convenient to give a shorthand for the normalization "constant", so we set:

$$N(z) = \sum_{k=1}^{n} e^{z_k} \tag{1.2}$$

## 1.1 Example

Figure 1 shows the softmax function applied to the set  $\{1, 2, 3, \dots, 8\}$ . As is evident, comparatively small values are given much less overall weight than higher ones.

### 2 Derivative

We might now want to differentiate with respect to the component  $z_j$ , which is done by applying the quotient rule:

$$\frac{\partial \sigma_i(z)}{\partial z_j} = \frac{\partial}{\partial z_j} \frac{e^{z_i}}{N(z)} = \frac{\left(\frac{\partial}{\partial z_j} e^{z_i}\right) N(z) - e^{z_i} \left(\frac{\partial}{\partial z_j} N(z)\right)}{(N(z))^2}$$
(2.1)

#### Softmax for {1, 2, 3, 4, 5, 6, 7, 8}

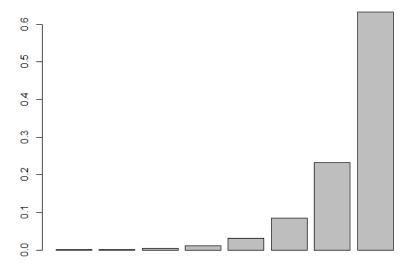

Figure 1: Softmax example

The two derivatives are:

$$\frac{\partial}{\partial z_j} e^{z_i} = \delta_{ij} e^{z_i}, \quad \frac{\partial}{\partial z_j} N(z) = \sum_{k=1}^n \delta_{jk} e^{z_k} = e^{z_j}$$
 (2.2)

Inserting into equation 2.1 this yields:

$$\frac{\delta_{ij}e^{z_j}N(z) - e^{z_i + z_j}}{(N(z))^2}$$
 (2.3)

The numerator can be rewritten:

$$e^{z_i} \left( \delta_{ij} N(z) - e^{z_j} \right) \tag{2.4}$$

Now divide by N(z) twice, once "outside the parenthesis" and once "inside" to get:

$$\frac{\partial \sigma_i(z)}{\partial z_i} = \frac{e^{z_i}}{N(z)} \left( \delta_{ij} - \frac{e^{z_j}}{N(z)} \right) = \sigma_i(z) \left( \delta_{ij} - \sigma_j(z) \right) \tag{2.5}$$

The likeness to the derivative of the logistic function should be evident.

# 3 Cross-entropy error function

The softmax is often combined with a cross-entropy error function for classification:

$$J(z) = \sum_{i=1}^{n} t_i \log \sigma_i(z) = \sum_{i=1}^{n} t_i \log y_i$$
 (3.1)

Here  $t_i$  represents the label for the data and  $y_i = \sigma_i(z)$  is the softmax output. For classification, this is simply  $t_i = \delta_{ic}$ , where c is the correct label. In this case, the error function is simply:

$$J(z) = \sum_{i=1}^{n} \delta_{ic} \log \sigma_i(z) = \log \sigma_c(z) = y_c$$
 (3.2)

The derivative with respect to  $z_i$  is found through the chain rule:

$$\frac{\partial J}{\partial z_i} = \frac{\partial J}{\partial y_c} \frac{\partial y_c}{\partial z_i} = \frac{\partial}{\partial z_i} \log \sigma_c(z) \frac{\partial \sigma_c}{\partial z_i} = \frac{1}{\sigma_c(z)} \sigma_c(z) \left(\delta_{ci} - \sigma_i(z)\right) = \delta_{ic} - y_i \quad (3.3)$$

But this is exactly the difference between the real value  $t_i$  and the output  $y_i$ , also known as the error  $\delta_i = t_i - y_i$ :

$$\frac{\partial J}{\partial z_i} = \delta_i \tag{3.4}$$
